

House Price Prediction - Project Summary

The housing price prediction project used Linear Regression and Random Forest Regression models to estimate house prices based on property features. After cleaning and encoding the dataset, both models were trained and evaluated on unseen test data. The Random Forest model achieved better accuracy and a higher R^2 score, indicating stronger predictive performance.

Feature importance analysis showed that area, number of bathrooms, parking availability, air conditioning, and number of stories had the greatest influence on house prices. Larger homes with more amenities generally had higher market values.

One interesting observation was that some amenities contributed more to price than expected, while certain location-related features had a smaller impact. Based on the results, a real estate company should prioritize property size and key amenities when estimating market value and advising clients.
